REVIEW ARTICLE

Echocardiography in Early Pregnancy

Carmina Comas Gabriel, Pilar Prats Rodríguez

ABSTRACT

Within the last decade, two significant events have contributed to the increasing interest in early fetal echocardiography. First, the introduction of high frequency vaginal ultrasound probes allows detailed visualization of cardiac structures at early stage of gestation, making early detection of fetal malformations possible. Second, the close relationship observed between some first trimester sonographic and Doppler markers and congenital heart defects allows an early identification of a high-risk group at 11 to 14 weeks of gestation. In this context, from the early 1990s, many authors have examined the potential role of the transvaginal approach to obtain earlier diagnosis of fetal cardiac malformations. Further studies have appeared in the literature showing that early transvaginal echocardiography in experienced hand is a fairly sensitive investigative tool. Although some malformations are detected as early as 11 weeks' gestation, the optimal gestational age to perform the early scan is at least 13 weeks' gestation. Transvaginal ultrasound is the preferred approach, although most of the authors agree that results can be improved if transabdominal ultrasound is also incorporated. The further application of color Doppler enhances visualization. The sensitivity and specificity of early fetal echocardiography for the detection of heart anomalies is acceptable compared to the ones obtained by mid-gestational echocardiography, showing a slight reduction in detection rates and an increase in false positive and negative rates. The cardiac anomalies detected at this early stage of pregnancy are mainly defects involving the four-chamber view, indicating that defects solely affecting the outflow tracts are difficult to diagnose in the first trimester of pregnancy. Heart defects diagnosed early in pregnancy tend to be more complex than those detected later, with a higher incidence of associated structural malformations, chromosomal abnormalities and spontaneous abortions. The neonate follow-up or postmortem examination in case of termination of pregnancy (TOP) is essential to assess the actual role of early fetal echocardiography. At present, early fetal echocardiography is a promising technique, which can be of considerable value for patients at high-risk. This technique is, however, currently limited to a few specialized centers.

The aim of this review is to explore the possibilities of examining the fetal heart at this early stage of pregnancy. This article also present our experience in the first multicenter trial in early fetal echocardiography performed in Spain. In accordance with other studies, this experience stresses the usefulness of early echocardiography when performed by expert operators on fetus specifically at risk for cardiac defects. Our review of these additional 48 cases contributes to the expanding literature on the ability of transvaginal ultrasonography to detect fetal heart defects in early pregnancy.

INTRODUCTION

Prenatal detection of fetal congenital heart defects (CHD) remains the most problematic issue of prenatal diagnosis.[1] Major CHD are the most common severe congenital malformations, with an incidence of about 5 in a thousand live births, whenever complete ascertainment is done and minor lesions are excluded.[1,2] Congenital heart anomalies have a significant effect on affected children's life with up to 25 to 35% mortality rate during pregnancy and the postnatal period, and it is during the first year of life, when the 60% of this mortality occurs. Moreover, major CHD are responsible for nearly 50% of all neonatal and infant deaths due to congenital anomalies, and it is likely to be significantly higher if spontaneous abortions are considered. Although CHD use to appear isolated, they are frequently associated with other defects, chromosomal anomalies and genetic syndromes. Their incidence is 6 times greater than chromosomal abnormalities and 4 times greater than neural tube defects.[1-3]

Most major CHD can be diagnosed prenatally by detailed transabdominal second trimester echocardiography at 20 to 22 weeks' gestation.[1,3-6] The identification of pregnancies at high-risk for CHD needing referral to specialist centres is of paramount importance in order to reduce the rate of overlooked defects.[6,7] However, the main problem in prenatal diagnosis of CHD is that the majority of cases take place in pregnancies with no identifiable risk factors. Therefore, there is wide agreement that cardiac ultrasound screening should be introduced as an integral part of the routine scan at 20 to 22 weeks. When applied to low-risk population, scrutiny of the four-chamber view allows only the detection of 40% of the anomalies while additional visualization of the outflow tracts and the great arteries increase the rate up to 60 to 70%.[3-5]

Recently, the finding of an increased nuchal translucency[8,9] or an altered ductus venosus blood flow[10,11] at 10 to 14 weeks' gestation have been associated with a high-risk for CHD and their prevalence increase exponentially with the thickness of nuchal translucency[8] regardless of the fetal karyotype. Since earlier diagnosis of congenital malformations is increasingly demanded, the option of an early fetal echocardiography must be taken into account.[12-14] The use of high-frequency vaginal ultrasound probes along with substantial improvements in magnification and processing of the imaging, together with

the introduction of color Doppler, have extensively contributed to the development of the technique, allowing better visualization of cardiac structures earlier in pregnancy.[12,15,16] Although most of the groups perform early fetal echocardiography between 13 and 16 weeks' gestation, we can name it as so when performed before the 18th week of gestation. Despite several studies that stated that fetal heart examination could be incorporated in first or early second trimester examinations, its use is currently still limited to a few specialized centers.

TECHNICAL ISSUES

Regarding early fetal echocardiography, some institutions use predominantly the transvaginal approach[14,17-22] while others prefer the transabdominal one.[23-26] Most of the authors reporting early fetal echocardiography prefer the transvaginal approach due to its increased resolution associated with higher frequency transducers and also because given that equivalent transducers frequencies, the transvaginal probes provide better quality images.[27] However, most importantly, authors with background training as pediatric cardiologists are more likely to use the transabdominal approach in contrast with most of obstetricians, who are well used to the transvaginal route. The superiority of transvaginal sonography is usually well accepted before the 14th week. Between the 15th and 18th week both transabdominal and transvaginal routes seem to offer similar advantages and disadvantages, and beyond the 18th week the transabdominal echocardiography seems to achieve better results.[1,5,16,27,28]

The combination of two-dimensional (2D) echocardiography with color Doppler flow imaging proved generally helpful, in particular by visualization of blood flow on both great arteries and of two divided ventricular inflows. The addition of color Doppler flow studies provides substantial improvement in the diagnostic accuracy of early echocardiography, as was also shown by DeVore for transabdominal sonography in the second-half of pregnancy.[29]

When performing early fetal echocardiography, we firstly recommend scanning by the transvaginal route, following the examination by the transabdominal probe when a complete study is not possible. The highest frequency must always be used, whatever the route is chosen. Obviously, a high resolution real-time ultrasound has to be used. For color Doppler evaluation, the energy output levels have to be lower than 50 mW/cm^2 spatial peak temporal average. Since color Doppler is dissipated over a wide area of interest, thermal effects resulting from Doppler insonation should not be a matter of concern, unlike pulsed Doppler in which the whole energy of the beam is focused at a specific location. Besides, the embryonic developmental of the heart has been completed by the time the scan is performed.

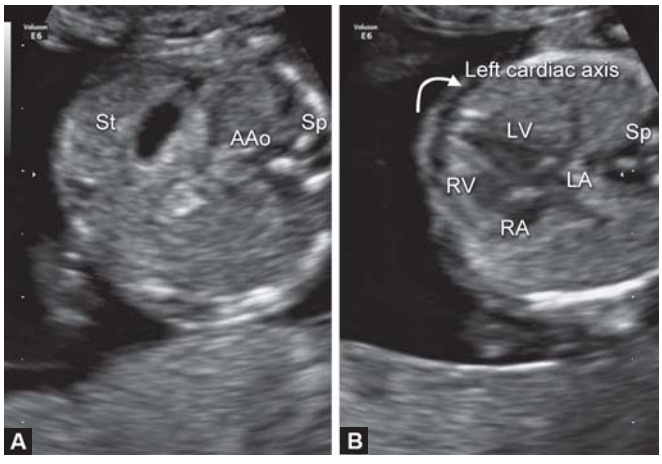
ULTRASOUND ANATOMY OF THE NORMAL HEART

Embryonic heart beat can be detected as early as the fifth week of gestation, and normal development of its function shows an increasing heart rate from 80 to 90 beats per minute at 5 weeks' gestation to 170 to 180 beats per minute at the end of the 9 to 10th week. As pregnancy progresses, the control of the heart rate matures with increasing vagal dominance, and the baseline rate declines to 145 to 155 beats per minute with the appearance of beat to beat variation, most likely resulting from the functional adaptation to the development of the heart and autonomic nervous system maturation, and remains more or less constant during the rest of intrauterine life.[30,31]

The structural development of the heart begins on day 16 and it is finished by the 10th week. Early fetal echocardiography has the same goals that the standard one and we advocate to perform it in a segmental approach. The first objective of the examination is to assess the normality of the four-chamber view through a transverse section of the fetal chest: Normal situs solitus; normal size and axis of the heart in relation to the chest; both atria equal in size, with the foramen ovale flapping within the left atrium; both ventricles equal in size and contractility; atrial and ventricular septa are of normal appearance; tricuspid and mitral valves are normally inserted, opening and closing together. Color and pulsed Doppler are particularly useful to confirm normal inflow to the ventricles and to detect turbulent flow or jets suggesting valve regurgitation. It is useful to assess the four-chambers in different views: apical, basal and long axis with the interventricular septum perpendicular to the ultrasound beam in order to visualize better the integrity of the septum. Then, the origin and double crossing of the great arteries must be correctly identified: the left ventricle outflow tract, with the continuity between the interventricular septum and the anterior wall of the ascending aorta; the right ventricle outflow tract, more superior, anterior, almost perpendicular to the axis of the ascending aorta and connecting to the descending aorta in the three vessels view**.** Color Doppler is also of help to better visualize the outflow tracts confirm anterograde flow through the semilunar valves and great arteries, and makes easier the examination of both aortic and ductal archs and their confluence. Pulsed Doppler may be used to assess blood flow through the aortic and pulmonic valves in order

to confirm normal anterograde flow and to detect very high velocities suggesting valve stenosis. Finally, color and pulsed Doppler are also very useful to identify normal systemic and pulmonary venous return. Figures 1 to 10 illustrates images obtained at early fetal scan by 2D echocardiography and color Doppler in a structurally normal heart. In our experience, the average duration of the complete fetal cardiac scan is over 15 minutes. It essentially depends on the gestational age at the examination, and can be even shorter if there is a favorable fetal lie. In our setting, a subsequent transabdominal echocardiography is scheduled for all our patients at 20 to 22 weeks' gestation.

Most of the authors agree that the best window of time to perform the early echocardiography is between the 13 and 16 weeks of gestation, since a complete cardiac examination is rarely achieved before the 13th week of gestation.[14,17,18,20-22,26] Articles on early fetal echocardiography demonstrate an increase in visualization rates of the four-chamber view and the outflow tracts in the last decade, with visualization rates greater than 90% at 13 weeks' gestation.[28] To maximize the reduction of uninterpretable examinations, early fetal echocardiography should be preferably performed at 13 completed weeks' gestation. Using current technology, the four-chamber view and the outflow tracts are often demonstrated by 2D echocardiography only, but color Doppler imaging enhances and makes the identification of the structures faster, increasing the success rate of the examination and allows even earlier identification of the structures.



Figs 1A and B: Early fetal echocardiography by 2D in a structurally normal heart. Situs visceral: Abdominal (A) and cardiac situs (B). Left: Fetal stomach, cross section of the abdominal aorta, spine and liver. Right: 4 chambers view. Heart axis pointing left, heart occupies one third of the thorax, majority of heart in left chest—RV: right ventricle; LV: left ventricle; RA: right atrium; LA: left atrium; AAo: aorta abdominal; St: stomach; Sp: spine

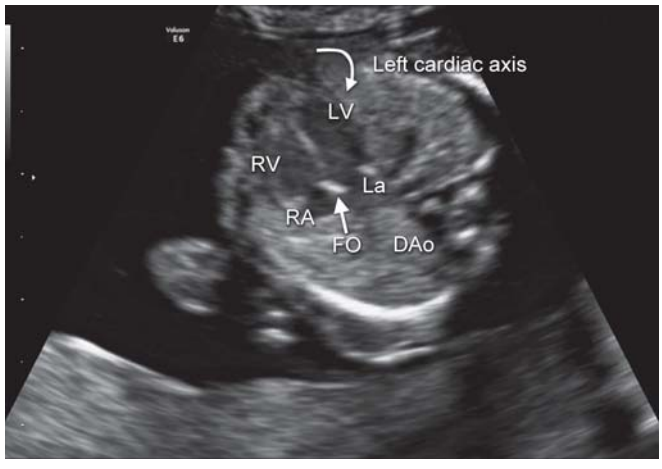


Fig. 2: Early fetal echocardiography by 2D in a structurally normal heart. The 4 chambers view: Normal situs solitus; normal size and axis of the heart in relation to the chest; both atria equal in size, with the foramen ovale flapping within the left atrium; both ventricles equal in size and contractility; atrial and ventricular septa are of normal appearance; tricuspid and mitral valves are normally inserted. RV: right ventricle; LV: left ventricle; RA: right atrium; LA: left atrium; FO: foramen ovale; DAo: descending aorta

Fig. 3: Early fetal echocardiography by 2D in a structurally normal heart. Color Doppler in the 4-chamber view is particularly useful to confirm normal inflow to the ventricles and to detect turbulent flow or jets suggesting valve regurgitation. RV: right ventricle; LV: left ventricle; RA: right atrium; LA: left atrium

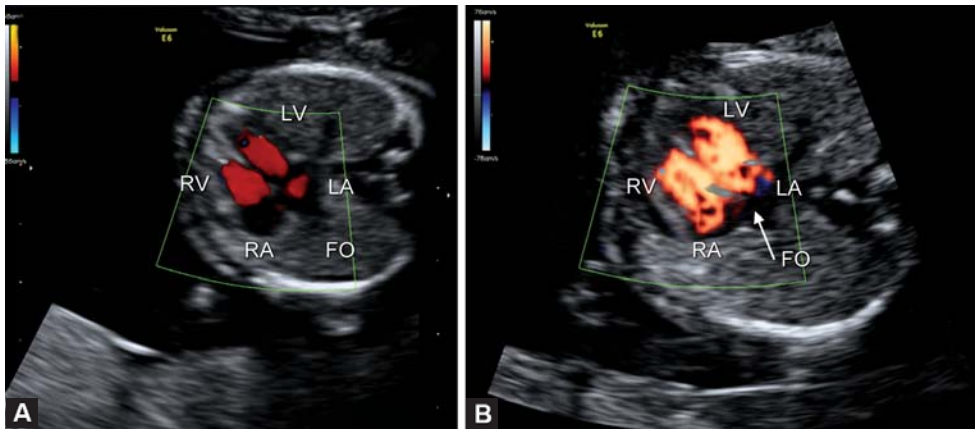
DIAGNOSIS OF CHD

The first diagnosis of a CHD by early echocardiography was reported by Gembruch et al[32] in 1990. A complete atrioventricular canal defect, with complete heart block and atrioventricular valve regurgitation was diagnosed at 11 weeks + 4 days' gestation using a 5 MHz transvaginal probe. The same year, Bronshtein et al[33] reported the diagnosis of a ventricular septal defect with overriding aorta and a further



Figs 5A and B: Early fetal echocardiography by 2D and color Doppler and bi-flow in a structurally normal heart. The 4-chamber view. (A) 4-chamber view—2D and color Doppler. (B) 4-chamber view—2D and bi-flow. RV: right ventricle; LV: left ventricle; RA: right atrium; LA: left atrium; FO: foramen ovale; DAo: descending aorta

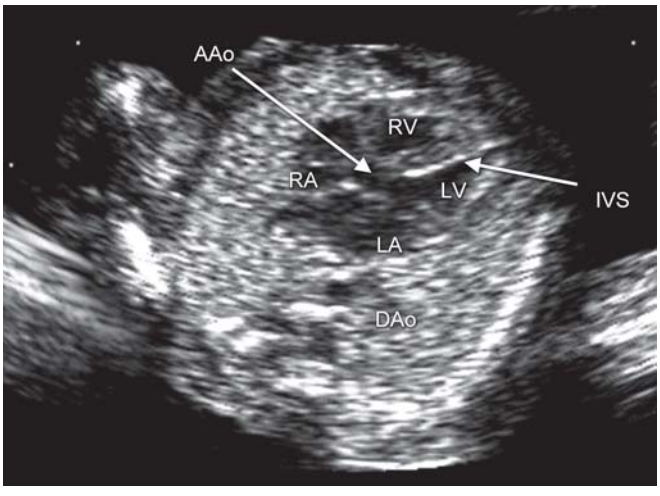


Fig. 6: The 5-chamber view: Left ventricle outflow tract in the long axis view showing the continuity between the interventricular septum and the anterior wall of the ascending aorta. RV: right ventricle; LV: left ventricle; RA: right atrium; LA: left atrium; AAo: ascending aorta; DAo: descending aorta; IVS: interventricular septum

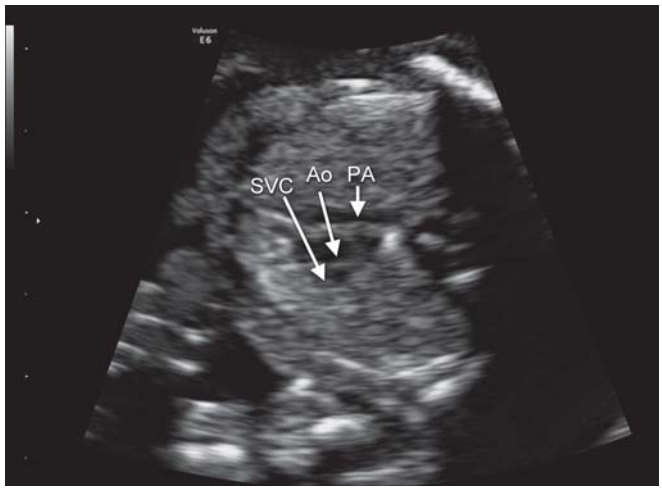

Fig. 7: Early fetal echocardiography by 2D in a structurally normal heart. The 3 vessels view: Cross-sections of the pulmonary artery, ascending aorta and superior vena cava in a transverse view of upper mediastinum. In normal conditions, the structures in the 3 vessels view are in descending order of size from left to the right. PA: pulmonary artery; Ao: aorta; SVC: superior vena cava

Figs 8A to C: Early fetal echocardiography by 2D, color Doppler and bi-flow in a structurally normal heart. Color Doppler is particularly useful to demonstrate the normal V confluence of the ductal and aortic archs (V sign). Note that normally the trachea is located behind the aortic arch (A) 3 vessels view by 2D, (B) 3 vessels view by 2D and color Doppler, (C) 3 vessels view by 2D and bi-flow

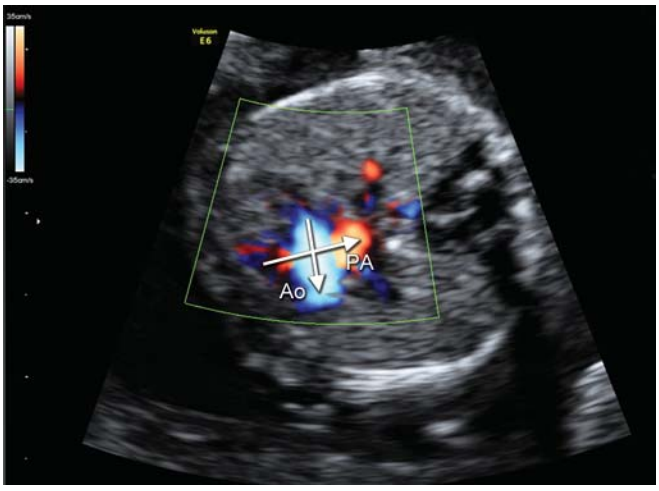

Fig. 9: Early fetal echocardiography by 2D and bi-flow in a structurally normal heart. Bi-flow is particularly useful to demonstrate the crossing of the great arteries. Ao: aorta; PA: pulmonary artery

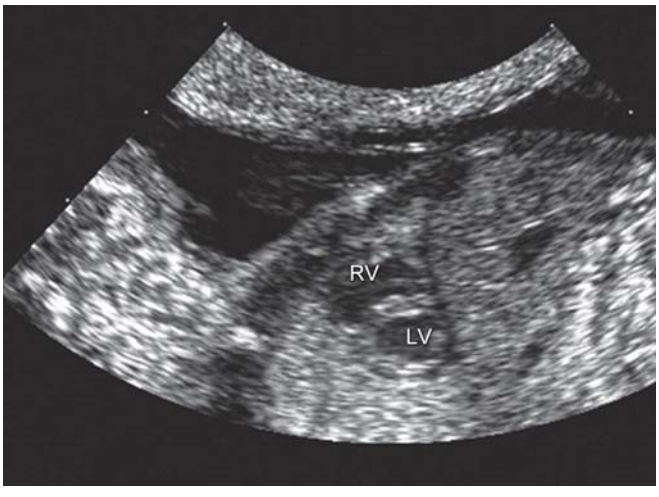

Fig. 10: Early fetal echocardiography by 2D in a structurally normal heart**.** The short axis view showing an anterior right ventricle and a posterior left ventricle. RV: right ventricle; LV: left ventricle

case of an isolated ventricular septal defect with pericardial effusion, both cases at 14 weeks' gestation. Since then, an increasing number of case reports and series on the early diagnosis of CHD have been reported, both in high-risk and low-risk population. Tables 1 and 2 summarizes some of the largest and most significant studies on the detection of CHD using early fetal echocardiography in high-risk and low-risk pregnancies.[14,17-22,24-26,34-46] Obviously, studies in unselected population report less encouraging results, with lower visualization rates and detection rates. The largest series was published by Bronshtein et al.[20] They report the diagnosis of 173 cases of CHD over 36,323 fetuses evaluated by transvaginal ultrasound at 11 to 17 weeks' gestation over a 14-year period of time, with 99% of scans performed at 14 to 16 weeks' gestation and 86% of them in low-risk population. Two institutions went further and reported their experience performing the echocardiography as early as between 10 and 13 weeks' gestation.[22,26]

The most frequent fetal heart anomalies diagnosed at early echocardiography are summarized in Table 3 (true positive cases).[14,18-21,24-26,34,35,37,39-42,45,46] Note that only the main anomaly for each fetus is presented in the table, even though some fetuses had several cardiac anomalies. It should be noted that defects such a small isolated ventricular septal defect or valvular stenosis are not reported in these studies. Table 4 summarizes the published cases of cardiac anomaly not detected in early pregnancy (false negative cases).[14,19-21,24-26,34-37,39-42,45,46]

The results of these studies support the use of early fetal echocardiography to detect the majority of major CHD in both low-risk and high-risk population, during the first and early second trimester of pregnancy. The cardiac anomalies detected at this early stage of pregnancy are mainly defects

involving the four-chamber view, such as large ventricular septal defects, atrioventricular septal defects and malformations resulting in asymmetry of the ventricles, indicating that defects solely affecting the outflow tracts are difficult to diagnose in the first trimester of pregnancy. Heart defects diagnosed early in pregnancy tend to be more complex than those detected later, with a higher incidence of associated structural malformations, chromosomal abnormalities and spontaneous abortions. It is widely accepted that the spectrum of CHD diagnosed during prenatal life is different from that observed in postnatal series, with a higher incidence of associated extracardiac lesions and a significant relationship with chromosomal abnormalities in comparison with postnatal life.[3-5,17] Furthermore, when the cardiac defects are detected during the early pregnancy, they use to be even more complex, probably corresponding to the most severe spectrum of the disease[21,25,26] and use to cause more severe hemodynamic compromise in the developing fetus. A common finding is the presence of an hygroma or hydrops associated with

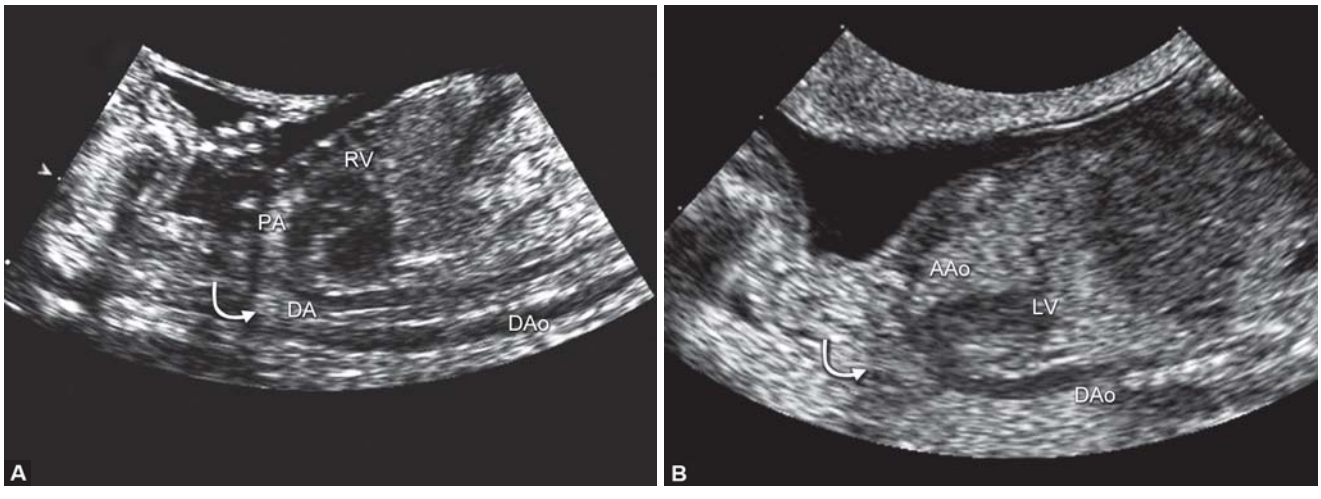
CHD, whereas this is not so when the diagnosis is done later in pregnancy.[1,5,21] As a result, many of these fetuses are not going to survive long into the second trimester, but this does not argue against early diagnosis. Indeed, when the intrauterine demise of the fetus occurs days or weeks before the delivery, the pathological examination is certainly more difficult to perform. All these considerations should be taken into account when counseling the parents about complex CHD.

We have previously published our experience in the first multicenter trial in early fetal echocardiography performed in Spain[21] (Figs 11 to 15). In accordance with other studies, this experience stresses the usefulness of early echocardiography when performed by expert operators on fetus specifically at risk for cardiac defects. Our review of these additional 48 cases contributes to the expanding literature on the ability of transvaginal ultrasonography to detect fetal heart defects in early pregnancy. Figures 16 to 23 show early fetal echocardiography in structurally abnormal heart.

ADVANTAGES AND LIMITATIONS

The first benefit of performing early fetal echocardiography would be an early reassurance of normality in order to relieve anxiety and reduce emotional trauma to the parents



Figs 11A and B: Early fetal echocardiography by 2D in a structurally normal heart. The left sagittal view of ductal (A) and aortic arch (B). RV: right ventricle; LV: left ventricle; PA: pulmonary artery; DA: ductus arteriosus; DAo: descending aorta; AAo: ascending aorta

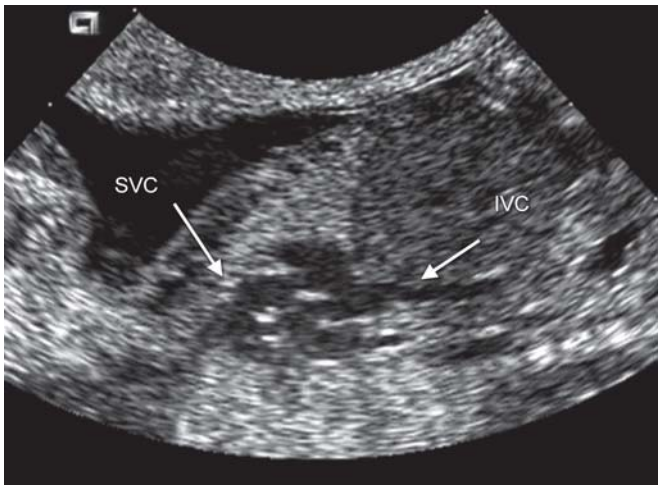


Fig. 12: Early fetal echocardiography by 2D in a structurally normal heart. Systemic venous return to the right atrium throws the superior and inferior vena cava. SVC: superior vena cava; IVC: inferior vena cava

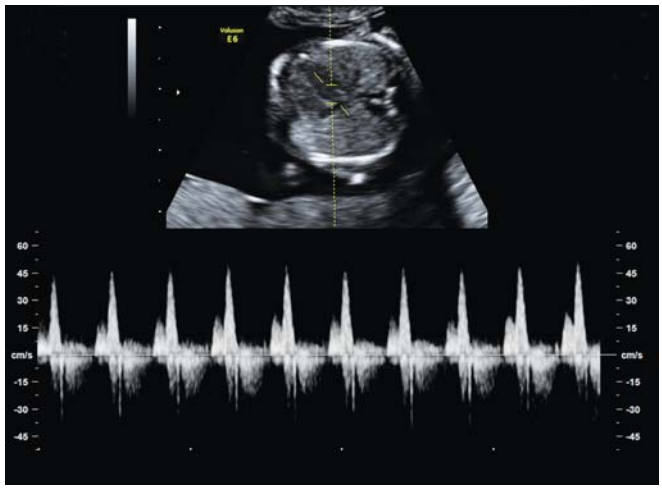

Fig. 14: Early fetal echocardiography by 2D and power Doppler. Normal mitral wave flow by power Doppler

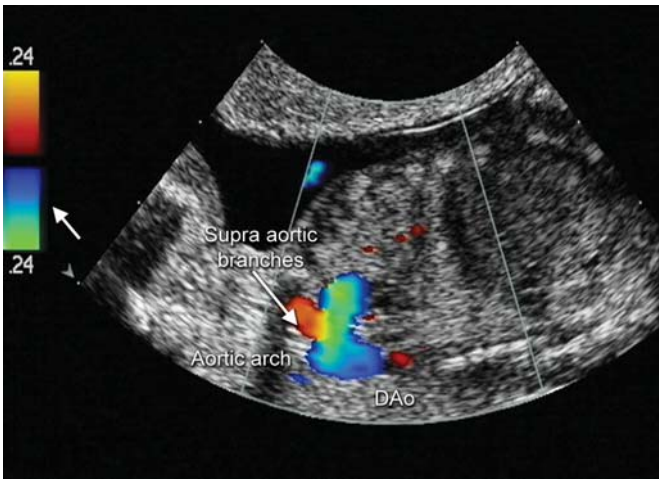

Fig. 13: Early fetal echocardiography by 2D and color Doppler in a structurally normal heart. Color Doppler is particularly useful to demonstrate the aortic arch. DAo: descending aorta

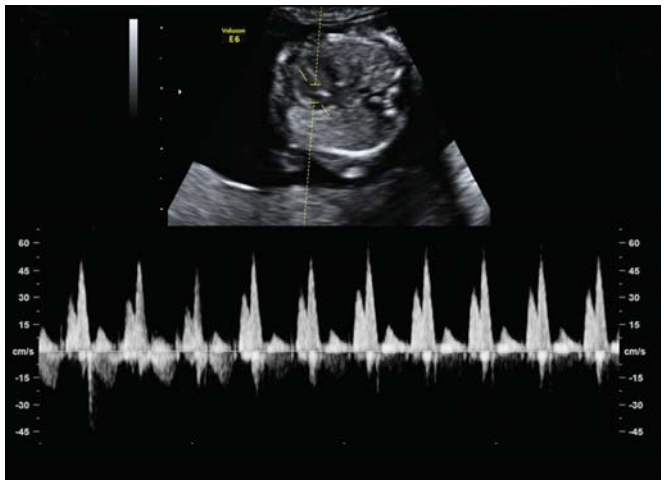

Fig. 15: Early fetal echocardiography by 2D and power Doppler. Normal tricuspid wave flow by power Doppler

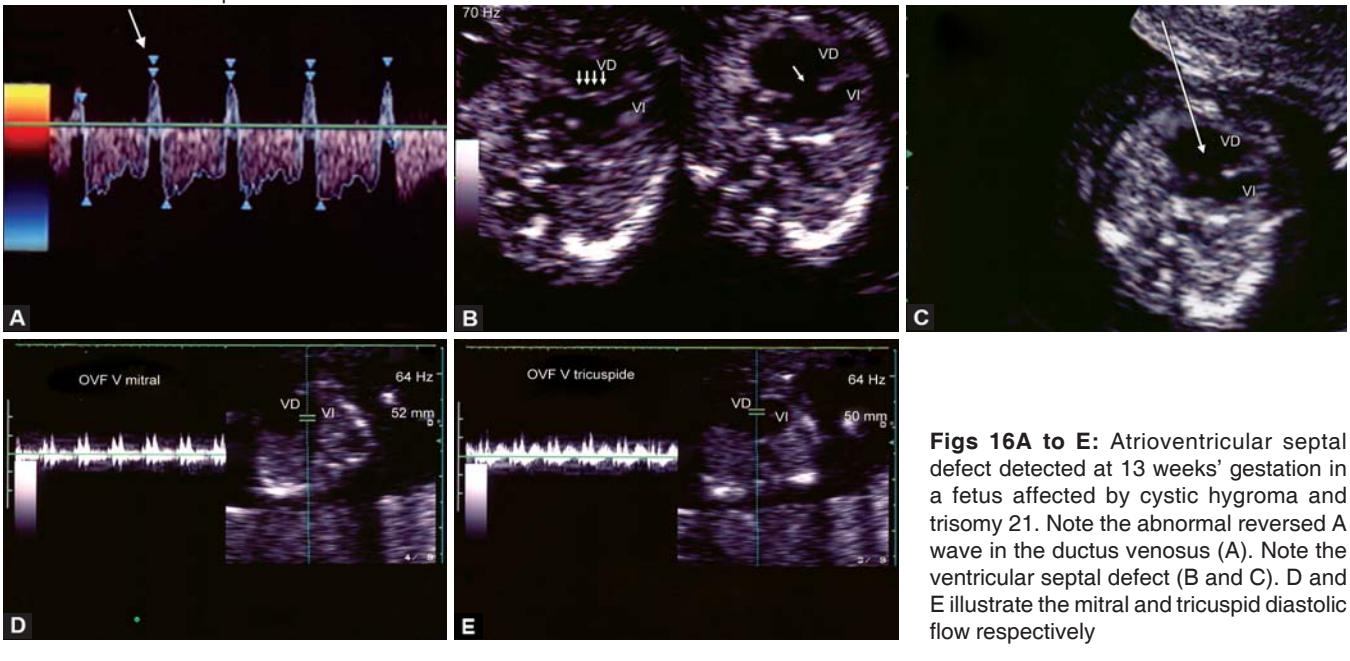
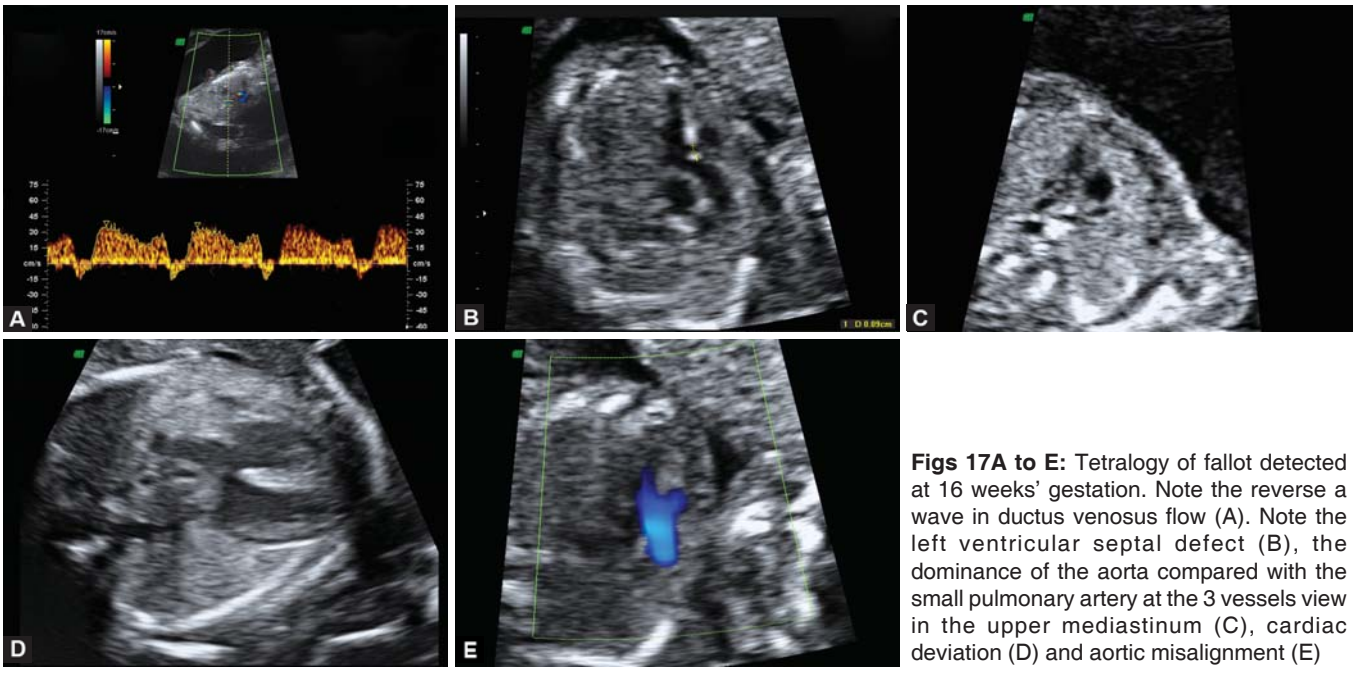
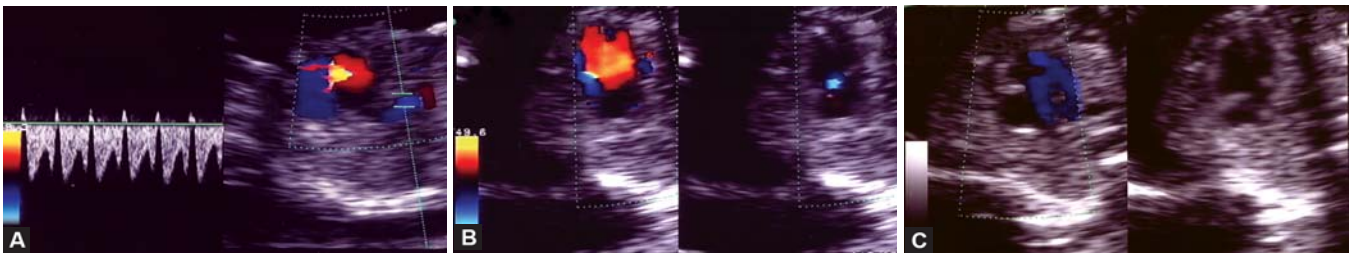
Atrioventricular septal defect



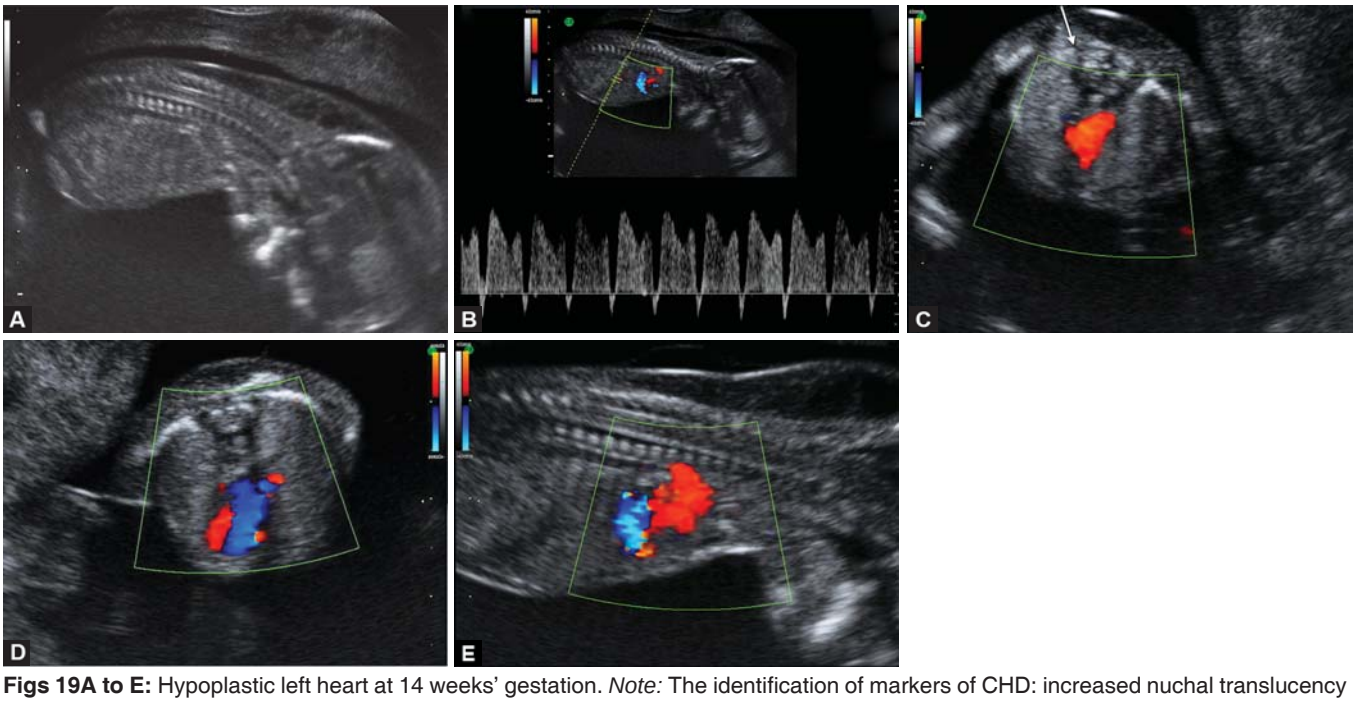
Figs 16A to E: Atrioventricular septal defect detected at 13 weeks' gestation in a fetus affected by cystic hygroma and trisomy 21. Note the abnormal reversed A wave in the ductus venosus (A). Note the ventricular septal defect (B and C). D and E illustrate the mitral and tricuspid diastolic flow respectively



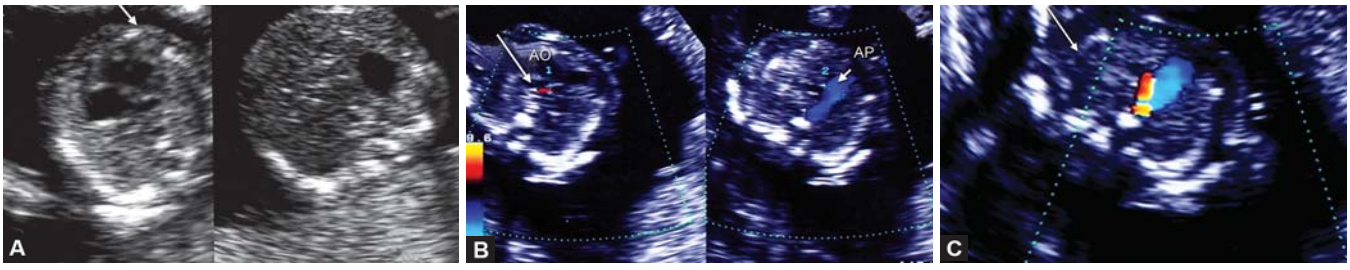
Figs 17A to E: Tetralogy of fallot detected at 16 weeks' gestation. Note the reverse a wave in ductus venosus flow (A). Note the left ventricular septal defect (B), the dominance of the aorta compared with the small pulmonary artery at the 3 vessels view in the upper mediastinum (C), cardiac deviation (D) and aortic misalignment (E)



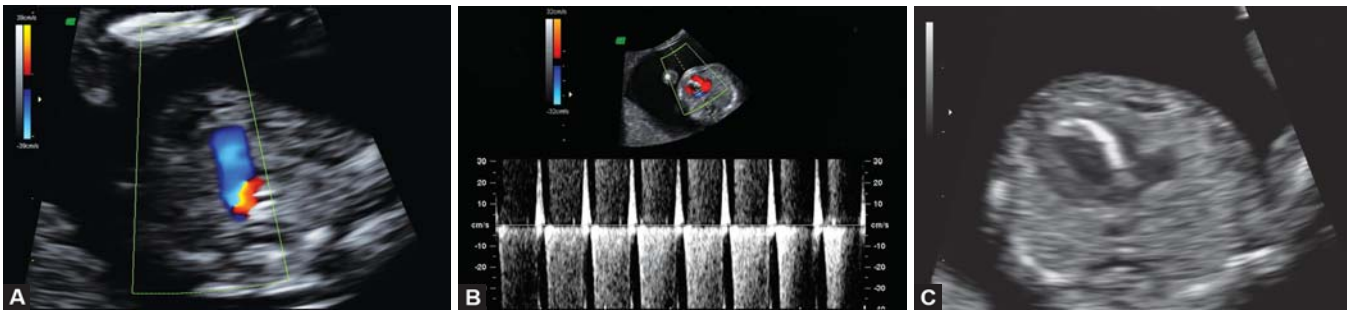
Figs 18A to C: Atrioventricular septal defect with unbalanced right ventricle dominance and double outlet right ventricle at 15 weeks' gestation. *Note*: The abnormal reversed A wave in the ductus venosus (A), the color Doppler flow through the atrioventricular septal defect with atrioventricular regurgitation (B) and the double outlet right ventricle with unbalanced right ventricle dominance (C)



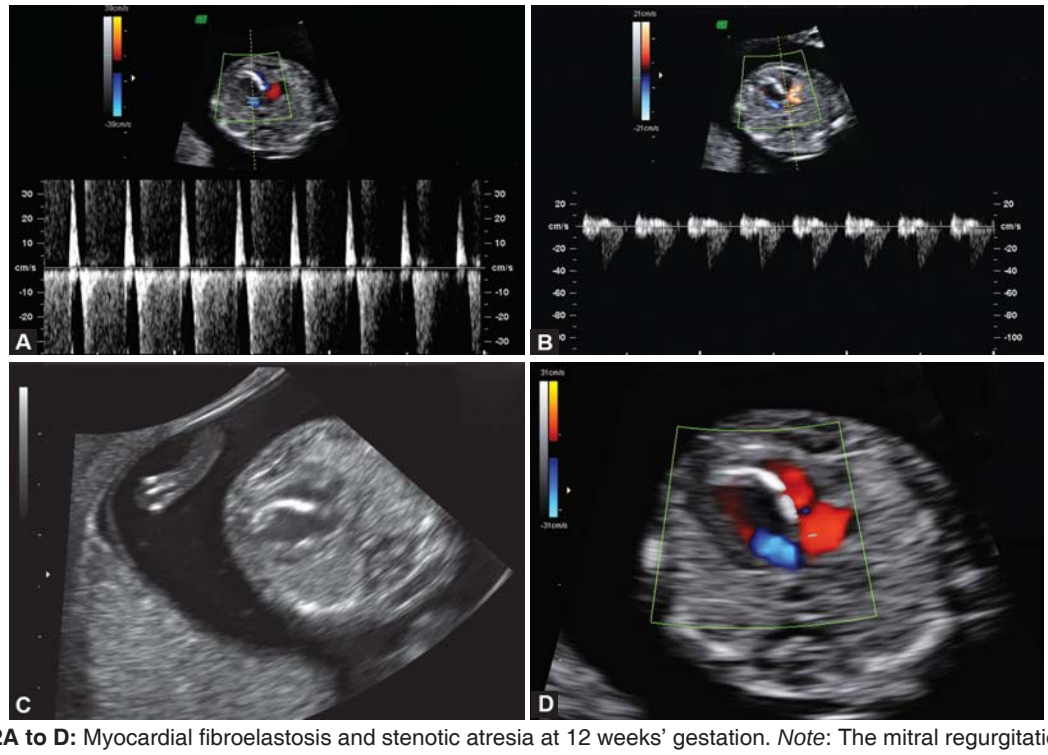
Figs 19A to E: Hypoplastic left heart at 14 weeks' gestation. *Note:* The identification of markers of CHD: increased nuchal translucency (A) and abnormal ductus venosus flow (B). Reverse flow at the 3 vessels view (C), hypoplastic left ventricle with reverse flow with color Doppler (D), reversed flow in aortic arch (E)



Figs 20A to C: Hypoplastic left heart and aortic stenosis at 17 weeks' gestation in a Turner syndrome. *Note*: The left cardiac axis deviation (A), the severe reduction of the aortic outflow tract compared to the main pulmonary artery (B) and the opposite color flow in the V sign at the upper mediastinum level (C)



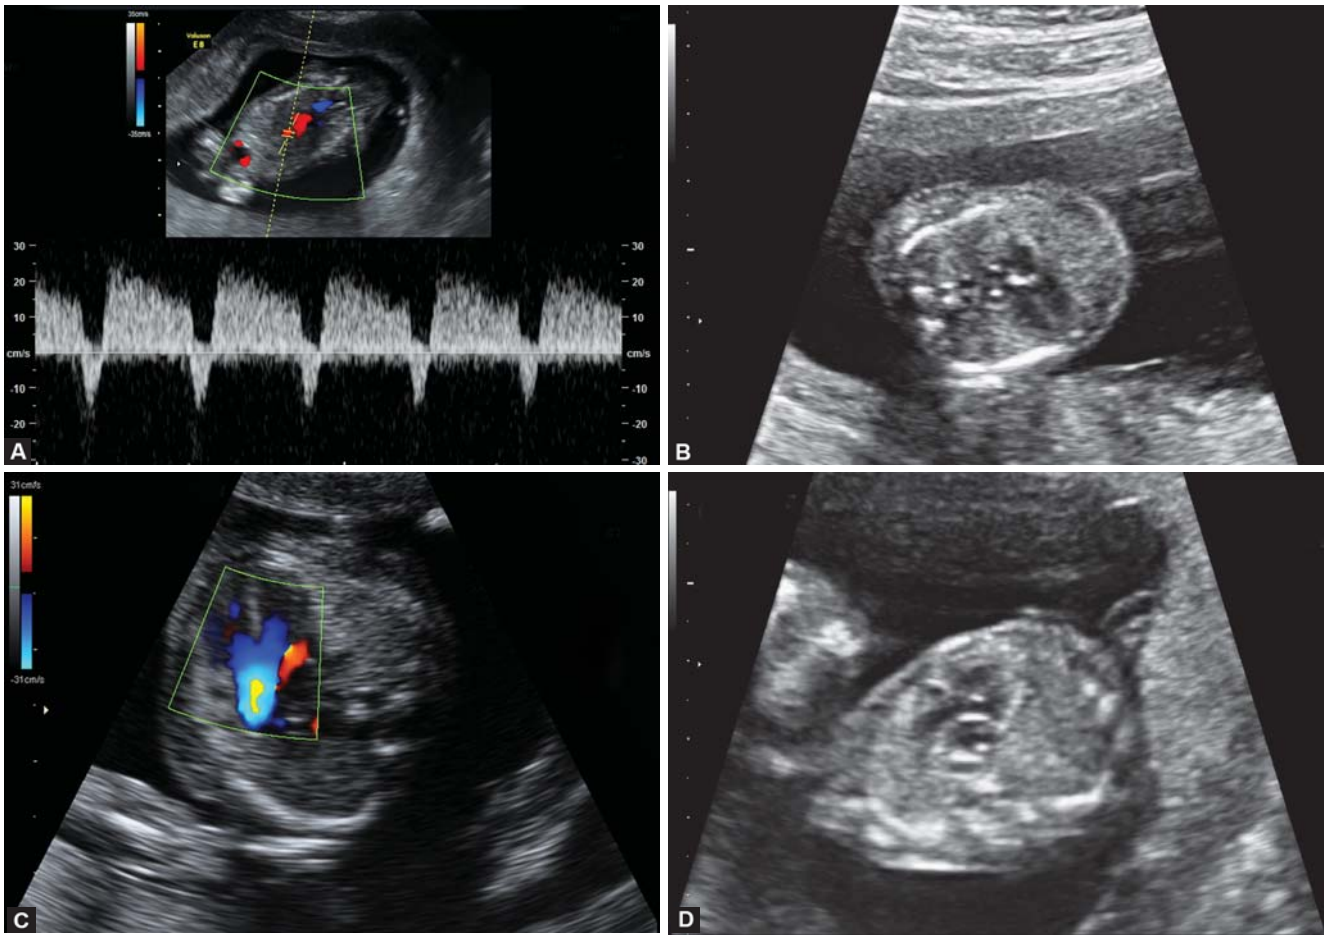
Figs 21A to C: Myocardial fibroelastosis and stenotic atresia at 12 weeks' gestation. *Note*: Aortic reverse flow in 3 vessels view (A), mitral regurgitation (B) and myocardial fibroelastosis (C)



Figs 22A to D: Myocardial fibroelastosis and stenotic atresia at 12 weeks' gestation. *Note*: The mitral regurgitation and the fibroelastosis (A) and the reverse flow in pulmonary veins (B), myocardial fibroelastosis in 2D (C) and color Doppler (D)

at high-risk for CHD. Early prenatal diagnosis of CHD will allow us to optimize the genetic counseling to the parents by permitting further testing such as fetal karyotyping and in those cases with severe defects it may provide the parents with the option of an earlier and safer TOP.[13,14,17] In selected cases, there is the possibility of pharmacologic therapy. Furthermore, the correct timing and place for delivery may be planned and arranged well in advance.

However, there are certain disadvantages of the early scanning which reduce its diagnostic accuracy compared with the conventional examination at 20 to 22 weeks' gestation.[1,5,13,14,17] The transvaginal technique requires a



Figs 23A to D: Tetralogy of fallot at 16 weeks. *Note*: Abnormal ductus venosus flow (A), the ventricular septal defect (B), aorta misalignment and reverse flow in pulmonary artery (C) and dilatation of the aorta (D)

substantial amount of operator experience, yet it cannot be learned from the second trimester examination as the early transabdominal scan. Unfavorable fetal position or limited angles of insonation due to the less mobile capacity of the transvaginal probe may not overcome. Also, spatial orientation can be challenging by the transvaginal scan. In such cases, we recommend a transabdominal scan that will help us to quickly asses the situs and obtain a good spatial orientation. The small size of the fetal heart is an important limiting factor to obtain an optimal sonographic visualization, and also to obtain a successful pathological examination, particularly before the 13th week of gestation. At 13 to 14 weeks of gestation the transverse diameter of the heart at the four-chamber view ranges between 5 and 8 mm, and the great artery diameter at the level of the semilunar valves ranges between 0.8 and 1.8 mm.[5] Moreover, this exploration is more time consuming and requires a high level of training of the examiner. Finally, the biggest disadvantage of first-trimester echocardiography is the later manifestation of structural and functional changes in some CHD. Some cardiac lesions are progressive in nature, such as mild pulmonary and aortic stenosis or coarctation and even hypoplastic left heart syndrome. Some obstructive lesions, as a result of a reduced blood flow, may increase the severity of the lesions, resulting in a restricted growth in chambers or arteries. This may be the biggest disadvantage of performing the early scan. Progression usually is toward a more severe form of lesion that may be sometimes only discernible in the second or even in the third trimester, although in some rare cases a regression to a less severe form may be observed. In this sense, the false negative cases published in literature are particularly instructive demonstrating these limitations. Another disadvantage of early fetal echocardiography is the possible detection of defects that could resolve spontaneously in later pregnancy, such as muscular ventricular septal defects, resulting in unnecessary anxiety in the parents.

Therefore, a normal early examination does not preclude a subsequent abnormal heart development at the second trimester ultrasound, or even in the third trimester or the postnatal period. After a normal early fetal echocardiography, a conventional transabdominal echocardiography at 20 to 22 weeks of gestation is strongly recommended.

PATHOLOGICAL CONFIRMATION

Pathological confirmation in the case of an early TOP or perinatal death is particularly important in those areas where ultrasound diagnosis is most challenging. Only a complete diagnosis will make an individual genetic counseling possible and will validate the accuracy of early fetal echocardiography as a diagnostic technique. Therefore, we advocate that a precise pathological report have to be compulsory for an adequate assessment of the reliability of early fetal echocardiography. This is still a major drawback in most of the studies.[1,5,21,26]

TOP is an option only before 22 weeks of gestation in our country. Whenever a termination takes place, it is of vital importance to obtain permission for autopsy in order to confirm the diagnosis and to search for any other associated malformations. Ideally this should be performed by a pathologist who is familiar with the small size of the specimen and with special examination techniques such as dissection microscopy.[5,21,22] Current methods of terminating early pregnancies others than using prostaglandins are less recommended because do not usually allow the retrieval of suitable specimens for appropriate examination to correlate ultrasound and pathological findings. This method allows a more gentle extraction of the embryo or fetus so that a pathological examination for verification of the prenatally diagnosed malformation can be performed. A pathological investigation after TOP following the diagnosis of a CHD should be always recommended, preferably in referral laboratories, being of paramount importance to validate early echocardiography. In particular semilunar valve and aortic arch defects are usually underdiagnosed. We are aware of some cases in which Doppler findings, such turbulent flow and very high velocities, are more reliable to diagnose valve stenosis than pathological examination, even during the second trimester. Indeed, this is a problem and a major challenge not only for ultrasonographers but also for pathologists.

INDICATIONS OF EARLY FETAL ECHOCARDIOGRAPHY

Since most CHD are detected in low-risk pregnancies, and knowing the high prevalence of heart defects in a nonselected population (incidence of CHD in low-risk population 1\238),[20] some authors suggest that an early detailed cardiac examination should be performed in all pregnant women.[17,20] Indeed, very few cardiac defects have been identified in the pregnancies in which a family history was the main indication for the early fetal echocardiography, which is consistent with the recurrence rate of 2 to 3% for siblings. The main value of the early scan in such family-risk cases lies in the reassurance that it gives to the parents. As we have previously stated, in most of the studies the early echocardiography is somewhat less reliable and may result in a higher false-negative and false-positive results in comparison with the 20 to 22 weeks transabdominal echocardiography. Besides, early echocardiography is most time-consuming and requires a high level of expertise of the examiner. Therefore, it is difficult to offer this scan as a screening test to the general population. In this context, the identification of a high-risk collective is of paramount importance.

Currently, the importance of the aforementioned limitations of early fetal cardiac examination justifies restriction of its use to fetuses at high-risk of having cardiac anomalies.[5,10,14,18,21,22,26,47]

The indications proposed for early fetal echocardiography are as follows:

- Increased nuchal translucency (>95th or 99th percentile) is the main indication of referral in all recently reported studies
- Abnormal ductus venosus blood flow, regardless the measurement of the nuchal translucency
- Fetuses affected by other structural malformations: Hygroma, hydrops, omphalocele, situs inversus, arrhythmia
- Monochorionic placentation in multiple gestation
- Suspected cardiac anomalies at screening ultrasound
- Pregestational diabetes of the mother
- High-risk family, with a previously affected child, a first-degree relative affected by a congenital heart disease or a genetic disease in which CHD are common
- Women at high-risk of chromosomal abnormality declining invasive test for karyotyping
- Pregnancies affected by a chromosomal abnormality.

Currently, as long as the sensitivity, specificity and predictive value of early echocardiography are still unclear, this examination should be generally reserved for patients at high-risk for CHD. However, only the accumulation of results from carefully collaborative studies as the present series will clear define the role of early transvaginal echocardiography.

CONCLUSION

Fetal echocardiography performed by expert operators is reliable for an early reassurement of normal cardiac anatomy.

1. Transvaginal sonography enables good visualization of fetal heart earlier in gestation. The four-chamber view

and the extended examination to the great vessels can be imaged in almost 100% at 13 to 14 weeks of gestation. Less than 5% of patients will need a repeated scan because of inadequate visualization.

2. The combination of transvaginal and transabdominal routes and the application of color Doppler enhance visualization.
3. Most CHD are detected in low-risk population. As we can not perform a targeted fetal echocardiography as a screening test, we need to improve the identification of high-risk group pregnancies. Increased nuchal translucency at 10 to 14 weeks' scan and, may be, ductus venosus blood flow assessment seem to be the newest and most promising risk factors for fetal CHD, and may be particularly useful during the first trimester.
4. Currently, early fetal echocardiography should be offered to high-risk pregnancies. Some authors advocate routine early extended cardiac examination in low-risk pregnancies. At present, as long as the sensitivity, specificity and predictive value of early echocardiography is still unclear, this examination should be generally reserved for patients at high-risk for CHD.
5. Whenever a normal heart is diagnosed in the early scan, it has to be supplemented with the conventional transabdominal examination at 20 to 22 weeks' gestation.

Fetal echocardiography performed by expert operators is reliable to diagnose most major structural heart defects in the first and early second trimester of pregnancy.

1. Cardiac defects diagnosed early in pregnancy tend to be more complex than those detected later on and use to cause more severe hemodynamic compromise in the developing fetus.
2. Many CHD can be detected at the beginning of the second trimester.
3. The incidence of associated structural malformations, chromosomal abnormalities and spontaneous abortions is significantly high.
4. A complete work-up including pathological and karyotype evaluation should be warranted in order to provide parents with a proper genetic counseling, which is extremely difficult to obtain if spontaneous loss of the pregnancy occurs.
5. The small size of specimens at this time of gestation renders pathological examination difficult and requires high expertise and careful inspection, irrespective of the technique used for termination.
6. Clinical follow-up in the neonate and postmortem examination if TOP is undertaken are essential to assess the actual role of early fetal echocardiography.
