Gynecological Tumors Image using High Definition Ultrasound (HDlive US)

Fernando Bonilla-Musoles, Francisco Raga, Francisco Bonilla Jr, Juan Carlos Castillo, Oscar Caballero Luna

ABSTRACT

Abdominal and/or vaginal two-dimensional (2D) and three-dimensional (3D) ultrasound (US) are the ‘gold standard’ technology on which diagnosis and control of gynecological tumors depend.

In recent years a series of software that initially generated enormous interest, have been introduced to improve 2D/3D US image quality and diagnostic accuracy. Many of them have shown limited interests.

The last one and the most interesting is HDlive which incorporates a movable virtual adjustable light that, as it penetrates, produces selective illumination with respective shadows that result from the structures where light is reflected. This combination of lights and shadows results in spectacular images which are much more real than those obtained with conventional 3D US.

This note simply pretends to show the quality of images obtained in cases of gynecological tumors using this easy-to-handle high definition ultrasound technology.

INTRODUCTION

Vaginal two-dimensional (2D) ultrasound (US) is the gold standard technology on which diagnosis, control and management in gynecological tumors is based.

In order to increase image quality, in recent years a series of software has been introduced, but with scarce application possibilities and in limited areas.

The most recent and promising is HDlive which incorporates a movable virtual adjustable light source which, as it penetrates, produces selective illumination with respective shadows that result from the structures where light is reflected. This combination of lights and shadows results in spectacular images which are much more real than those obtained with conventional 3D US.

During the past year, we have examined dozens of images generated by 2D/3D US of benign and malignant ovarian and endometrial tumors using 3D HDlive imaging (E8, GE® Medical System, Kretz, Zipf Austria).

HDlive images were obtained using a special software that calculates light propagation through surface structures in relation to light direction. The transducer uses a second generation dynamic rendering rotor and calculates the data obtained in a graphic processing unit with a power that is 20 times superior to the ones currently in use.

Based on specific case reports of gynecological tumors, we are showing the improvement in image quality using this new software.

UTERUS

The uterine (Fig. 1) and endometrial morphology (Fig. 2) can be examined as well as with 2D or 3D US, but the quality of the obtained images is clearly superior if 3D US is used.

Two/three-dimensional US scans can be employed in the follow-up of the endometrial receptivity in all cases of follicular development, endometrial tumors (Fig. 3), endometrial hyperplasias and malignancy (Fig. 4).

The increased quality supposes a better and easier diagnostic potential of, for example, cases of adenomyosis, miomatosis and müllerian malformations.

FALLOPIAN TUBES

The most frequent tube pathologies are salpingitis and its chronic consequence the hidrosalpinx (Fig. 5). Other tumors and cancer are very infrequent.

Acute salpingitis, especially if it contains pus, appears as a pelvic inflammatory disease with numerous irregular cysts of different sizes and forms containing a gray content.

Chronic adnexitis, sactosalpinx and hidrosalpinx, appears as pure cysts of different forms and sizes always ecocative and located around the ovaries or behind the uterus.

In many cases, as the present image (see Fig. 5) the tubal walls are thickened.
ADNEXAL TUMORS

Pure ovarian cysts (Fig. 6), endometriomas (Fig. 7) and teratomas (Fig. 8) are the most common benign ovarian tumors.

Pure cysts arise normally from the coelomic epithelium of the ovarian surface, called epithelium germinalis, which give rise to 85% of all ovarian tumors (the so-called cysto-adenomas and cystocarcinomas).

They are characterized by a unique, round, well delimited, and with homogeneous inner cyst surface (see Fig. 6).

Endometriomas are the consequence of retrograde menstruation and endometrial cell implantation in the ovarian surface, and many other places (see Fig. 7). Its pathognomonic ecographic appearance is a cystic wall containing a homogenous-gray echo, the differential diagnosis must be done with infected cysts or dermoid tumors.

MULTICYSTIC OVARIAN TUMORS

Although many of these are benign tumors, a careful examination is mandatory in order to rule out malignant features.

1. The inner zone: must be ‘pure’ cysts without internal echoes.

2. The shape, size and thickness of the septums: must be homogeneous and smooth septums free of endophitic papillae.

3. Absence of papillae, typically seen in malignancy.

4. Other features of malignancy: ascitis, exophytic tumors, metastasis, etc. Besides having a low incidence, its big mortality rates makes it the worst cancer in female. HDlive may help to increase the diagnostic accuracy. Herein, we show three interesting cases (Figs 8 and 9).

TERATOMAS

These tumors are derived from the primordial germinal cells which are located on the germinal line starting from the primitive gut primordial ovary on the germinal epithelium. Teratomas are usually located on the sacro-coxis and ovary, and contains full-developed tissues derived from the three germinal layers (ectoderm, mesoderm, and endoderm).

The great majority are bening; however, many of them present aggressive behavior and early metastasis.

The ultrasonographic appearance of teratomas are cystic images containing echogenic heterogeneous masses (fat and sebaceous content), and hyperechogenic zones corresponding to bone tissue.
The following images of a typical case show a clear visualization of all these structures including teeth, hair, fatty tissue and bones (Fig. 10).

**OVARIAN CANCER**

Neither all solid (or solid/cystic) tumors of ovarian localization are malignant nor persistent. Also, not all the ‘anechogenic’ cystic masses are benign, exceptionally they may be ‘borderline’ or malignant tumors.

Over 90% of malignant ovarian neoplasm show ultrasonographic features able to conclude in a correct diagnosis or at least able to ‘alert’ the clinician toward a high index of suspicion.

The ‘quality’ of the ecographic image is of the outmost importance to clarify the diagnosis, especially in atypical cases.

The majority of ovarian cancers are composed from a mixture of solid and solid-cystic parts. Mostly of the irregular cystic components are formed by necrotic cancer tissue (Fig. 11).
Fig. 5: Two-dimensional orthogonal view and HDlive depicting a distended fallopian tube sequelae of a chronic salpingitis. HDlive clearly shows the thickened wall dilated tube and its econegative content (also known as sactosalpinx). There are no septums or papillae, but it is not unfrequent to observe them as a consequence of inflammation of the mucosa folds.

Fig. 6: Pure ovarian cyst depicted in three orthogonal planes and HDlive. Compare the view of the inner cyst wall using these two US different modes.

DISCUSSION

Over the years, there have been efforts to improve 2D US image quality, but except for the switch from abdominal to vaginal route along with higher frequencies introduced during the early 1980s, there has been practically no substantial advances.

In recent years, a series of software has been introduced, but with scarce application possibilities and in limited areas. These modalities are the inverse mode, which special application for fluid-containing pathologies; the AVC mode (automatic volume calculation) important for antral follicle count and measurement of gynecological tumor volumes; the

Fig. 8: Ovarian serous cystadenoma with multicystic component. HDlive allows the study in several ecographic views. Note the high-definition image of the inner surface of the cysts. Translucency view is shown in the upper right image.
Fig. 9: Typical cyst with walls studied with 2D, 3D, VOCAL and HDlive. On the upper left image—when seen on 2D US—an structure resembling a mixed cyst over the septum can be observed. However, when HDlive is applied (bottom right image), it is finally concluded that it is only another small cyst.

Fig. 10: Orthogonal planes (upper) and 3D HDlive of a benign ovarian cystic teratoma or dermoid cyst depicted with maximum transparency and also showing the Rokitansky nodule containing bone and teeth.
A correct discrimination between benign and malignant pathology is mandatory for management and prognosis; most women with adnexal masses do not have cancer. The issue about finding an accurate and simple test for discriminating benign from malignant adnexal tumors has become like the Holy Grail of gynecological ultrasound research. A plethora of diagnostic models have been developed over the last two decades.

- Only ultrasound parameters (Ferrazzi, Finkler, Granberg, Sassone, De Priest, Lerner, Merz, Risk of Malignancy Index (RMI)).
- Two-dimensional ultrasound and 3D tumor volume measurement.
- Combined with 2D Doppler (Kurjak), Zannoni or with 3D Doppler angiography.
- US combined with various prediction models International Ovarian Tumor Analysis (IOTA).

Although all these parameters have been described in clinical practice to the best of our knowledge the most precise are RMI and the Mainz University criteria. However, the perfect marker is still to be defined.

The most recently described IOTA study, combined predictive models and ultrasonographic parameters; for regression model #1, twelve clinical/ecographic parameters are employed and for regression model #2, only six demographic and ecographic parameters were used.

Unexpectedly, there was substantial variability in the assessment of various measurements and categorical variables with substantial variability in the calculation of the malignancy risk. Nevertheless, none has gained universal acceptance in routine clinical practice, including the recent IOTA system, which showed that the diagnostic models performed well when used by experimented sonographers.

The agreement between operators was much better when they tried to determine the nature of adnexal tumors based on subjective assessment of ultrasound findings. Subjective assessment of ultrasound images by experienced clinicians is the best way to characterize ovarian and endometrial pathology. Many endometrial and adnexal masses have a typical ultrasound appearance and will be correctly classified as benign or malignant. Figure 10 is a clear example.

Fig. 11: Ovarian carcinoma observed with 2D US power Doppler, conventional 3D HDlive (upper left and bottom right) and maximal luminescence. Notice the clear view of the solid component and the papillae.
Many studies have addressed the relationship of the endometrial thickness and malignancy risk. It is generally accepted that below 3 mm there is no estrogenic effect or malignancy risk and, below 5 mm, the malignancy risk is almost negligible. However, several authors have described case reports of adenocarcinomas (almost always Mullerian in origin) with endometrial thickness below 3 mm.

In order to enhance diagnostic sensibility, some parameters were progressively introduced:

• The evaluation of the homogeneity
• The evaluation of delimitation
• Doppler study of endometrial vascularization.

A better knowledge and higher skills of ultrasonography techniques but also enhance of image quality is mandatory whether a diagnosis consensus in endometrial malignancy is pretended.

Summarizing, ultrasound knowledge and the better image quality are the best parameters to determine the benign or malignant nature. In this way, HDlive, by increasing image quality, offers new possibilities of extremely interest (see Figs 8 to 11).

Recent publications, most of them focused in obstetrics, show that HDlive provides a much more natural and realistic appearance of the normal embryo, fetuses, their facial expressions, cases of fetal abnormalities: acrania/exencephaly, cyclopia with proboscis, cystic hygroma, Omphalocele, multicystic kidney, persistent cloaca, siamese twins, TRAP syndrome and umbilical vein varix.

The most recent articles have been focused in visualizing special organs as heart, the uvula and the soft palate.

Pictures obtained were so beautiful that five of these images showed in the articles were selected as pictures of the ‘month’. Some other articles also show pictures of borderline and malignant ovarian tumors as well as endometrial pathology, showing the usefulness of this new technology in the gynecological field.

In assisted reproduction HDlive provided improved visualization of the growing follicle and its content (follicular fluid, cumulus oophorus), polycystic ovaries and hyperstimulation ovarian appearance.

The present article shows images of uterine and ovarian tumors. The images, apart from being beautiful and of much better quality, may be useful in helping patients to understand such processes, and may enhance patient-knowledge about their disease and also increase patient-physician communication.

HDlive use in obstetrics and gynecology by adding the combination of light and shadows results in spectacular, natural resembling; photo-like images that are much more realistic than the ones obtained using conventional 3D US.

This novel technology deserves further evaluation in clinical obstetrics and gynecological practice.
